7-1. INTRODUCTION

Under the general heading of program analysis we can find today two disciplines which, even though they have similar aims, differ in the means and tools they apply to the task of analysis. The first is the discipline of program verification. This is usually presented as the process of finding invariants of the program, or in other words fully characterizing the behavior of the program, discovering all the properties of all possible executions [Mann74, Cous77e]. As such, it is extremely ambitious and hence a priori doomed to failure on theoretical grounds for all but the most restricted program models.
Newtonian Program Analysis

. . .

1. INTRODUCTION

This paper presents a novel generic technique for solving dataflow equations in interprocedural dataflow analysis. It is obtained by generalizing Newton’s method, the 300-year-old technique for computing a zero of a differentiable function.

Our approach to interprocedural analysis is very similar to Sharir and Pnueli’s functional approach [Sharir and Pnueli 1981; Jones and Muchnick 1982; Knoop and Steffen 1992; Reps et al. 1995; Sagiv et al. 1996; Nielson et al. 1999; Reps et al. 2005]. Sharir and Pnueli assume the following as given: a (join-) semilattice of values, a mapping assigning to every program instruction a value, and a con-

Sufficient condition for existence of least solution: $(D, +, \cdot)$ is a
($\omega$-continuous) semiring
Solving the equations: Kleene iteration

Theorem [Kleene]: The least solution $\mu f$ of $X = f(X)$ is the supremum of $\{k_i\}_{i \geq 0}$, where

$$
\begin{align*}
    k_0 &= f(0) \\
    k_{i+1} &= f(k_i)
\end{align*}
$$

Basic algorithm: compute $k_0, k_1, k_2, \ldots$ until either $k_i = k_{i+1}$, which implies $k_i = \mu f$, or the approximation is considered adequate.
Kleene iteration is slow

Set domains: Kleene iteration never terminates for $X = f(X)$ if least solution $\mu f$ is an infinite set.

- $X = a \cdot X + b \quad \mu f = a^* b$
- Kleene approximants are finite sets: $k_i = (\epsilon + a + \ldots + a^i)b$

Probabilistic interpretation: convergence can be very slow for polynomial equations [EY STACS05].

- $X = \frac{1}{2} X^2 + \frac{1}{2} \quad \mu f = 1 = 0.99999\ldots$
- “Logarithmic convergence”: $k$ iterations to get $\log k$ bits of accuracy.

$$k_n \leq 1 - \frac{1}{n+1} \quad k_{2000} = 0.9990$$

Kleene vs. Newton

Program analysis:

• Kleene iteration is applicable to arbitrary $\omega$-continuous semirings
• ...but converges slowly.

Numerical mathematics:

• Newton’s Method converges fast
• ...but can only be applied to the real field
Kleene vs. Newton

Program analysis:

• Kleene iteration is applicable to arbitrary $\omega$-continuous semirings
• ...but converges slowly.

Numerical mathematics:

• Newton’s Method converges fast
• ...but can only be applied to the real field

Can Newton’s method be generalized to arbitrary $\omega$-continuous semirings?
Mathematical formulation of Newton’s Method

Elementary analysis yields for the $i$-th Newton iterant $\nu_i$:

\[
\begin{align*}
\nu_0 & = 0 \\
\nu_{i+1} & = \nu_i + \Delta_i
\end{align*}
\]

where $\Delta_i$ least solution of

\[
X = Df_{\nu_i}(X) + f(\nu_i) - \nu_i
\]

$Df_{\nu_i}(X)$ differential of $f(X)$ at the point $\nu_i$
Generalizing Newton’s method

Key point: generalize \( X = Df_\nu(X) + f(\nu) - \nu \)

to arbitrary \( \omega \)-continuous semirings

In an arbitrary \( \omega \)-continuous semiring

- neither the differential \( Df_\nu(X) \), nor
- the difference \( f(\nu) - \nu \)

are defined.
Overcoming the obstacles

(1) Use the algebraic definition of differential (recall that we only have polynomial functions!)

\[
Df(X) = \begin{cases} 
0 & \text{if } f(X) = c \\
X & \text{if } f(X) = X \\
Dg(X) + Dh(X) & \text{if } f(X) = g(X) + h(X) \\
Dg(X) \cdot h(X) + g(X) \cdot Dh(X) & \text{if } f(X) = g(X) \cdot h(X)
\end{cases}
\]

(2) Replace \( f(\nu_i) - \nu_i \) by any \( \delta_i \) such that \( f(\nu_i) = \nu_i + \delta_i \)

Define \( \Delta_i \) as the least solution of \( X = Df_{\nu_i}(X) + \delta_i \)
Idempotent and commutative semirings

Theorem [Hopkins-Kozen LICS ’99]: The least fixed point of a system $X = f(X)$ of $n$ equations over an idempotent and commutative $\omega$-continuous semiring is reached by the sequence

$$
\begin{align*}
\nu_0 &= f(0) \\
\nu_{i+1} &= J(\nu_i)^* \cdot f(\nu_i)
\end{align*}
$$

after at most $O(3^n)$ iterations.
Idempotent and commutative semirings

Theorem [Hopkins-Kozen LICS ’99]: The least fixed point of a system $X = f(X)$ of $n$ equations over an idempotent and commutative $\omega$-continuous semiring is reached by the sequence

\[
\nu_0 = f(0) \\
\nu_{i+1} = J(\nu_i)^* \cdot f(\nu_i)
\]

after at most $O(3^n)$ iterations.

Theorem: This is exactly Newton’s sequence.

Moreover, the fixed point is reached after at most $n$ iterations.
Two (quick) examples of application
listify(): transforms a binary tree of pointers into a list of pointers by reading the tree in preorder.

```cpp
void listifyL() {
    T.move_left();
    listify();
    T.move_up();
}

void listify() {
    L.push_back(T->get_data());
    if( T.is_leaf() == false ) {
        listifyL();
        listifyR();
    }
}
```
May-Alias Analysis
May-Alias Analysis
May-Alias Analysis

Which **data access paths** of tree and list may point to the same element?

Access path of the tree: word $w_1 \in \{\text{left}, \text{right}\}^*$

Access path of the list: word $w_2 \in \{\text{next}\}^*$

May-alias information: set of pairs $(w_1, w_2)$ such that $w_1, w_2$ may point to the same cell

**Commutative abstraction:** $(\text{left right left, next next}) \rightarrow (3, 1, 2)$
May-Alias Analysis

Kleene iteration does not terminate.

Newton’s method terminates after one iteration and provides the following information:

- Data access paths with 0 right’s and \( \ell \) left’s may only be aliased to the \( \ell \)-th element of the list.

- Data access paths with \( r \) right’s and \( \ell \) left’s may only be aliased to the \((2r + \ell)\)-th element of the list, or to larger elements of the same parity.
Lazy evaluation of And-Or trees

Nodes are only constructed and evaluated (to 0 or 1) if needed. (e.g., if left subtree of And-node evaluates to 1, right subtree is not constructed)

```
function And(node)
  if node.leaf() then
    return node.value()
  else
    v := Or(node.left)
    if v = 0 then
      return 0
    else
      return Or(node.right)
  end

function Or(node)
  if node.leaf() then
    return node.value()
  else
    v := And(node.left)
    if v = 1 then
      return 1
    else
      return And(node.right)
  end
```
Assume the probabilities that node.leaf() returns \textbf{true} and node.value() returns 1 are both \(1/2\).

We perform an analysis to compute the average runtime.
Neither Kleene nor Newton terminate, but Newton converges faster:

I. Introduction

Diverse graph structure models for concurrent processing systems have been suggested and used. The structures differ in generality and scope according to the properties one wishes to model and analyze. In this paper we solve a problem of maximal storage requirements for a simple flowchart model called the Marked Graph Model.
