Scoping and control structures
What can we name?

- execution point (labels)
- mutable variables
- values
- functions
- types
- type constructors (e.g., list or vector)
- classes
- modules/packages
- execution point with environment (continuation)
A *binding* is an association of two things. The first is usually a name. *Binding time* is the time at which the association is made. Binding times:

- Language design time: semantics of most language constructs
- Language implementation time: implementation dependent semantics
- Compile time
- Link time
- Run time

*Static* means before run time, *dynamic* means during run time.
**Scope**: the region of program text where a binding is active.

**Lifetime**: the period of time between the creation of an entity and its destruction.

Note that these talk about two different things.
For objects residing in memory, there are typically three areas of storage, corresponding to different lifetimes:

- **static** objects: lifetime of entire program execution
  - **globals**, **static** variables
- **stack** objects: from the time the function or block is entered until the time it is exited
  - **local variables**
- **heap** objects: arbitrary lifetimes, not corresponding to the entrance or exit of a function or block
  - dynamically allocated objects, e.g., with **new**
Two major scoping disciplines:

- **static**: binding of a name is given by its declaration in the innermost block
  - Most languages use some variant of this

- **dynamic**: binding of a name is given by the most recent declaration encountered
  - Used in Lisp, Snobol, APL
var x = 1;

function f () { print x; }

function g () { var x = 10; f(); }

function h () { var x = 100; f(); }

f(); g(); h();

<table>
<thead>
<tr>
<th>Scoping</th>
<th>Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>Static</td>
<td>1 1 1</td>
</tr>
<tr>
<td>Dynamic</td>
<td>1 10 100</td>
</tr>
</tbody>
</table>
What is the scope of \( x \)?

```plaintext
{
    statements1;
    var x = 5;
    statements2;
}
```

- C++, Ada: `statements2`
- Javascript: entire block
- Pascal: entire block, but not allowed to be used in `statements1`!
A *control structure* is any mechanism that departs from the default of straight-line execution.

- **selection**
  - if statements
  - case statements

- **iteration**
  - while loops (unbounded)
  - for loops
  - iteration over collections

- **other**
  - goto
  - call/return
  - exceptions
  - continuations
In machine language, there are no if statements or loops.  
We only have branches, which can be either unconditional or conditional (on a very simple condition).  
With this, we can implement loops, if statements, and case statements. In fact, we only need

1. increment  
2. decrement  
3. branch on zero

to build a universal machine (one that is Turing complete).

We don’t do this in high-level languages because unstructured use of the goto can lead to confusing programs. See “Go To Statement Considered Harmful” by Edgar Dijkstra.
if Condition then Statement – Pascal, Ada
if (Condition) Statement – C/C++, Java
To avoid ambiguities, use end marker: end if, “}”
To deal with multiple alternatives, use keyword or bracketing:

```plaintext
if Condition then
   Statements
elsif Condition then
   Statements
else
   Statements
end if;
```
if Condition1 then
    if Condition2 then
        Statements1
    end if;
else
    Statements2
end if;
Statement Grouping

- Pascal introduces begin-end pair to mark sequence
- C/C++/Java abbreviate keywords to \{ \}
- Ada dispenses with brackets for sequences, because keywords for the enclosing control structure are sufficient
- `for J in 1..N loop ... end loop`
  - More writing but more readable
- Another possibility – make indentation significant (e.g., ABC, Python, Haskell)
if \( \frac{x}{y} > 5 \) then \( z := \ldots \) -- what if \( y = 0 \)?
if \( y \neq 0 \) and \( \frac{x}{y} > 5 \) then \( z := \ldots \)

But binary operators normally evaluate both arguments. Solutions:

- a lazy evaluation rule for logical operators (Lisp, C)
  
  \[
  C1 \&\& C2 \quad // \text{don’t evaluate } C2 \text{ if } C1 \text{ is false} \\
  C1 \mid\mid C2 \quad // \text{don’t evaluate } C2 \text{ if } C1 \text{ is true}
  \]

- a control structure with a different syntax (Ada)
  
  \[
  \begin{align*}
  \text{if } C1 \text{ and then } C2 \text{ then } & -- \text{ if } C1 \text{ is false} \\
  \text{if } C1 \text{ or else } C2 \text{ then } & -- \text{ if } C1 \text{ is true}
  \end{align*}
  \]
Case statement needed when there are many possibilities “at the same logical level” (i.e. depending on the same condition)

```plaintext
case Next_Char is
  when 'I'    => Val := 1;
  when 'V'    => Val := 5;
  when 'X'    => Val := 10;
  when 'C'    => Val := 100;
  when 'D'    => Val := 500;
  when 'M'    => Val := 1000;
  when others => raise Illegal_Numeral;
end case;
```

Can be simulated by sequence of if-statements, but logic is obscured.
The Ada case statement

- no flow-through (unlike C/C++)
- all possible choices are covered
  - mechanism to specify default action for choices not given explicitly
- no inaccessible branches:
  - no duplicate choices (C/C++, Ada, Java)
- choices must be static (Ada, C/C++, Java, ML)
- in many languages, type of expression must be discrete (e.g. no floating point)
A possible implementation for C/C++/Java/Ada style case:

(If we have a finite set of possibilities, and the choices are computable at compile-time.)

- build table of addresses, one for each choice
- compute value
- transform into table index
- get table element at index and branch to that address
- execute
- branch to end of case statement

This is not the typical implementation for a ML/Haskell style case.
case (x+1) is
  when integer’first..0 => Put_Line("negative");
  when 1 => Put_Line("unit");
  when 3 | 5 | 7 | 11 => Put_Line("small prime");
  when 2 | 4 | 6 | 8 | 10 => Put_Line("small even");
  when 21 => Put_Line("house wins");
  when 12..20 | 22..99 => Put_Line("manageable");
  when others => Put_Line("irrelevant");
end case;

Implementation would be a combination of tables and if statements.
void send (int *to, int *from, int count) {
    int n = (count + 7) / 8;
    switch (count % 8) {
        case 0: do { *to++ = *from++; break; }
        case 7: *to++ = *from++; break;
        case 6: *to++ = *from++; break;
        case 5: *to++ = *from++; break;
        case 4: *to++ = *from++; break;
        case 3: *to++ = *from++; break;
        case 2: *to++ = *from++; break;
        case 1: *to++ = *from++; break;
    } while (--n > 0);
}
Indefinite loops

- All loops can be expressed as while-loops
  - good for invariant/assertion reasoning
- condition evaluated at each iteration
- if condition initially false, loop is never executed

```
while condition loop ... end loop;
```

is equivalent to

```
if condition then
  while condition loop ... end loop;
end if;
```

if *condition* has no side-effects
Sometimes we want to check condition at end instead of at beginning; this will guarantee loop is executed at least once.

- repeat ... until condition; (Pascal)
- do { ... } while (condition); (C)

while form is most common can be simulated by while + a boolean variable:

```plaintext
first := True;
while (first or else condition) loop
  ...
  first := False;
end loop;
```
A more common need is to be able to break out of the loop in the middle of an iteration.

- break (C/C++, Java)
- last (Perl)
- exit (Ada)

```
loop
  ... part A ...
  exit when condition;
  ... part B ...
end loop;
```
Sometimes, we want to break out of several levels of a nested loop

- give names to loops (Ada, Perl)
- use a goto (C/C++)

```
Outer: while C1 loop ...
    Inner: while C2 loop ...
        Innermost: while C3 loop ...
            exit Outer when Major_Failure;
            exit Inner when Small_Annoyance;
            ...
            end loop Innermost;
        end loop Inner;
    end loop Outer;
```

Definite Loops

Counting loops are iterators over discrete domains:

- `for J in 1..10 loop ... end loop;`
- `for (int i = 0; i < n; i++) { ... }`

Design issues:

- evaluation of bounds (only once, since Algol60)
- scope of loop variable
- empty loops
- increments other than 1
- backwards iteration
- non-numeric domains
for J in 1..N loop
    ...
    N := N + 1;
end loop; -- terminates?

Yes – in Ada, bounds are evaluated once before iteration starts. Note: the above loop uses abominable style. C/C++/Java loop has hybrid semantics:

for (int j = 0; j < last; j++) {
    ...
    last++; -- terminates?
}

No – the condition “j < last” is evaluated at the end of each iteration.
The loop variable

- is it mutable?
- what is its scope? (i.e. local to loop?)

Constant and local is a better choice:

- *constant*: disallows changes to the variable, which can affect the loop execution and be confusing
- *local*: don't need to worry about value of variable after loop exits

```plaintext
Count: integer := 17;
...
for Count in 1..10 loop
  ...
end loop;
...
-- Count is still 17
```
Different increments

Algol60:

\[
\text{for } j \text{ from } \text{exp1} \text{ to } \text{exp2} \text{ by } \text{exp3} \text{ do ...}
\]

- too rich for most cases; typically, \text{exp3} is +1 or -1.
- what are semantics if \text{exp1} > \text{exp2} and \text{exp3} < 0?

C/C++:

\[
\text{for (int } j = \text{exp1}; j \leq \text{exp2}; j += \text{exp3}) \text{ ...}
\]

Ada:

\[
\text{for } J \text{ in 1..N loop ...}
\]
\[
\text{for } J \text{ in reverse 1..N loop ...}
\]

Everything else can be programmed with a while loop
Non-numeric domains

Ada form generalizes to discrete types:

```plaintext
for M in months loop ... end loop;
```

Basic pattern on other data types:

- define primitive operations: `first`, `next`, `more_elements`
- implement for loop as:

```plaintext
iterator = Collection.Iterate();
element thing = iterator.first;
for (element thing = iterator.first;
    iterator.more_elements();
    thing = iterator.next()) {
    ...
}
```
How can we prove that a loop does what we want? *pre-conditions* and *post-conditions*:

\[
\{P\} \ S \ \{Q\}
\]

If proposition \(P\) holds before executing \(S\), and the execution of \(S\) terminates, then proposition \(Q\) holds afterwards.

Need to formulate:

- pre- and post-conditions for all statement forms
- syntax-directed rules of inference

\[
\{P \text{ and } C\} \ S \ \{P\}
\]

\[
\{P \text{ and } C\} \text{ while } C \text{ do } S \text{ endloop } \{P \text{ and not } C\}
\]
function Exp (Base: Integer; Expon: Integer) return Integer is

  N: Integer := Expon;  -- successive bits of exponent
  Res: Integer := 1;    -- running result
  Pow: Integer := Base;  -- successive powers: Base^{2^I}

begin
  while N > 0 loop
    if N mod 2 = 1 then
      Res := Res \* Pow;
    end if;
    Pow := Pow \* Pow;
    N := N / 2;
  end loop;
  return Res;
end Exp;
function Exp (Base: Integer;
              Expon: Integer) return Integer is
    N: Integer := Expon;  -- successive bits of exponent
    Res: Integer := 1;    -- running result
    Pow: Integer := Base;  -- successive powers: Base^{2^i}
begin
    {i = 0}  -- count iterations
    {i := i + 1}
    while N > 0 loop  -- ith bit of Expon from left
        if N mod 2 = 1 then
            Res := Res * Pow;  
            {Res := Base^{(Expon mod 2^i)}}
        end if;
        Pow := Pow * Pow;  
        {Pow := Base^{2^i}}
        N := N / 2;        
        {N := Expon/(2^i)}
    end loop;
    return Res;
end Exp;  
{\ i = \lg \ Expon; \ Res = Base^{\ Expon}; \ N = 0}
