Basic Algorithms, Assignment 2, Solutions

Due, Tuesday, Sept 18

Prof. Spencer's Office Hours: Wednesday 1-2:30
Course website:
`www.cs.nyu.edu/cs/faculty/spencer/basicalg/index.html`

1. If a computer does a billion operations per second how many does it do in a year. Round this to one significant digit and write it in exponential form, e.g., something like $3 \cdot 10^{43}$ (but thats not the answer!)
   Solution: We have $60 \cdot 60 = 3600$ seconds in an hour, $3600 \cdot 24 \sim 80000$ seconds in a day and $\sim 80000 \cdot 365 \sim 3 \cdot 10^7$ seconds in a year so the computer will do $\sim 10^9 \cdot 3 \cdot 10^7 = 3 \cdot 10^{16}$ operations in a year.

2. Redo Table 2.1 on Page 34 with the processor performing a billion operations per second and with functions $n, n \log_2 n, n^3, 1.1^n$.
   Solution: I give the time for input sizes resulting in a time greater than 1 second.
   n: < 1 sec, for each n
   $n \log_2 n$: < 1 sec for each n
   n^3: $n = 1,000$- 1 sec, $n = 10,000$-16min, $n = 100,000$-11 days, $n = 1,000,000$-32 years
   1.1^n: $n < 100$ - < 1sec, $n \geq 1000$ very long

3. Suppose an algorithm takes $n \log_2 n$ operations, and our computer does a billion operations per second. For how large an n can our computer do the algorithm in a day. (I'm looking for a *rough* answer here, say to one significant digit.)
   Solution: In a day the computer does $\sim 10^9 \cdot 80000 = 8 \cdot 10^{12}$ operations. Now the function $n \log_2 n$ does not have a nice exact inverse but the $\log_2 n$ term is nearly constant for long periods. As $\log_2 10^3 \sim 10$ (as $2^{10} = 1000$ except for roundoff error!) $\log_2 10^{12} \sim 40$. We want $n \log_2 n \sim 8 \cdot 10^{12}$ but $\log_2 n$ is around 40 so we want $n \sim 8 \cdot 10^{12}/40 = 2 \cdot 10^{11}$. Well, was our approximation OK? Actually $\log_2 n$ for this n is less than 40 but only by 2 or 3 so the approximation is pretty good.

4. How many binary digits are there in a 100 decimal digit number? (Actually, there are a few possible answers depending on the exact number but we're just looking for a rough answer.)
   Solution: Each 3 decimal digits give 10 binary digits so we get $10 \cdot 33 = 330$ binary digits from 10^{99} plus another three or four (or five or six)

from the remaining factor (between 10 and 99) so 335 would be a pretty good estimate.

5. Let $f(n) = \sqrt{2n \ln n}$ and let $g(n) = 6\sqrt{n}$. Which function is larger as for n sufficiently large? When does the eventually larger function become larger? (These functions actually came up in my work some years ago.)
   Solution: In comparing the $\sqrt{n}$ factors cancel so we are comparing $\sqrt{2 \ln n}$ with 6. As the first goes to infinity $f(n)$ is eventually larger. This occurs when $\sqrt{2 \ln n} = 6$, when $2 \ln n = 36$, when $\ln n = 18$, when $n = e^{18}$. Another handy estimate is that $e^3 \sim 20$ (they are very close!) so that $e^{18} \sim (20)^6 = 64000000$.

6. John Wastenot decides to implement the Stable Marriage Gale-Shapley algorithm without using much space. His input consists of linked lists of size n, `MANLIST`$[i]$, $1 \leq i \leq n$, and `WOMANLIST`$[j]$, $1 \leq j \leq n$, giving the preference list for each person of the opposite gender. He adds two array `MANMATE`$[i]$, $1 \leq i \leq n$, and `WOMANMATE`$[j]$, $1 \leq j \leq n$, giving the current mate `NIL` if there isn't one, which is the original value) of each person. He adds an array `MANLASTPROP`$[i]$ giving the last woman (`NIL` if there were none) that man i has proposed to.

   Write a pseudocode program for implementing Gale-Shapley with this data structure. Do a worst case analysis of how many steps the algorithm will take. (Note: The answer will *not* be $\Theta(n^2)$.)
   Solution (Outline): In the WHILE loop you go through i until finding `MANMATE`$[i]$ = `NIL`. If none is found, exit and print out couples. (This takes $\leq n$ steps.) Now go through `MANLIST`$[i]$ until finding `MANLASTPROP`$[i]$, let j be the next woman on `MANLIST`$[i]$. (This takes $\leq n$ steps.) (If `MANLASTPROP`$[i]$ = `NIL` let j be the first woman on `MANLIST`$[i]$.) Reset `MANLASTPROP`$[i] = j$. Now i proposes to j. The `WOMANMATE`$[j]$ case is now easy and quick. But when `WOMANMATE`$[j] = i' \neq$ `NIL` and we must see whether j prefers i or i'. To do that go through `WOMANLIST`$[j]$ until reaching either i or i', this taking $\leq n$ steps. The updating in the two cases is quick. The total time for the WHILE loop is now $\leq n + n = O(n)$. But the WHILE loop may be used n^2 time so this implementation has time $O(n^3)$. Note that this can be *considerably slower* than the implementation with time $O(n^2)$. This is a quite common occurance, that saving space by keeping auxilliary arrays to a minimum can lead to a great increase in time.

   Throughout human history, mankind has been a lot better at

gathering data than at thinking about it.
